# 1 Executive Summary

Commercial real estate appraisal firms face a fundamental pricing dilemma on every engagement: bid too high and lose the job; bid too low and win but leave revenue on the table. The **Bid Recommendation System** solves this with a dual-model machine learning approach that jointly optimizes bid pricing and win probability through **Expected Value (EV) maximization**.

The system comprises two independent LightGBM models operating in tandem:

- **Phase 1A (Regression):** Predicts the optimal bid fee given market context — “What should we charge?”
- **Phase 1B (Classification):** Predicts the probability of winning at that fee — “Will we win at this price?”

The combined metric  $EV = P(\text{Win}) \times \text{BidFee}$  drives recommendations. For example, a \$5,200 bid with 25% win probability ( $EV = \$1,300$ ) is objectively worse than a \$3,500 bid with 65% win probability ( $EV = \$2,275$ ). The system recommends the latter.

## Key results:

- Bid Fee model:  $R^2 = 0.972$ , RMSE = \$354, Median AE = \$35
- Win Probability model: AUC-ROC = 0.870, Accuracy = 79.0%, Overfitting ratio =  $1.09\times$
- Win probability model trained *with* BidFee as a feature — learns fee-sensitivity directly from data
- Data integrity: removed leaky job-derived features (JobCount, IECount, etc.) that inflated prior metrics
- LightGBM outperforms XGBoost by 12.8% (bid fee) and econometric panel models by  $>85\%$  on RMSE
- 68 carefully engineered features for bid fee, 72 for win probability, reduced from 84 via SHAP-based selection

The system is deployed as a full-stack web application: a React frontend on Vercel, a Flask API on Render, with LightGBM models in portable text format.

# 2 Problem Statement and Business Context

## 2.1 The Bid Pricing Challenge

In commercial real estate appraisal, firms submit competitive bids to win engagement contracts. Each bid represents a one-shot pricing decision with asymmetric consequences:

- **Overbidding:** Lose the engagement entirely — zero revenue.
- **Underbidding:** Win the engagement but at a suboptimal margin — reduced profitability.
- **Optimal bidding:** Maximize *expected* revenue across the portfolio.

Historically, bid pricing relied on appraiser judgment, historical norms, and ad hoc spreadsheet lookups. This approach suffers from:

1. **Inconsistency:** Different offices and appraisers price similar engagements differently.
2. **No win probability estimation:** Firms had no systematic way to estimate the likelihood of winning at a given price.
3. **No portfolio optimization:** Individual bids were priced in isolation, not in the context of expected revenue across all active bids.

## 2.2 Expected Value Framework

The system reframes bid pricing as an optimization problem:

$$EV(\text{fee}) = P(\text{Win} \mid \text{fee}, \text{context}) \times \text{fee} \quad (1)$$

This formulation captures the fundamental trade-off: higher fees increase per-deal revenue but decrease win probability. The optimal bid maximizes expected revenue. By combining predictions from both models, the system provides a principled recommendation that balances competitiveness with profitability.

## 3 Data Overview

### 3.1 Dataset Description

The dataset comprises bid records from a national commercial real estate appraisal firm spanning January 2018 through December 2025. After preprocessing, the system uses data from **January 2023 onward** (52,308 records) based on empirical evidence that a market regime shift makes older data counterproductive for generalization (see Section 9.1).

Table 1: Dataset Summary Statistics

| Attribute                         | Value   |
|-----------------------------------|---------|
| Total records (raw)               | 165,898 |
| Records after preprocessing       | 114,287 |
| Records used for training (2023+) | 52,308  |
| Training set (60%)                | 31,384  |
| Validation set (20%)              | 10,462  |
| Test set (20%)                    | 10,462  |
| Overall win rate                  | 48.7%   |
| Mean BidFee (2023+)               | \$3,363 |
| Median BidFee (2023+)             | \$3,000 |
| Standard deviation of BidFee      | \$2,131 |
| Unique offices                    | 50+     |
| Unique states                     | 50      |
| Unique property types             | 15+     |

### 3.2 Target Variable Characteristics

The target variable **BidFee** exhibits right-skewed distribution with a mean of \$3,363 and a long tail of high-value engagements. Extreme outliers (up to \$100M in raw data) were capped at the 99th percentile (\$15,000) during preprocessing.

Figure 1: Distribution of BidFee values after preprocessing, showing the right-skewed nature of engagement pricing.

### 3.3 Business Segment Distribution

The dataset is dominated by the **Financing** segment, which accounts for the vast majority of bid records. Understanding this distribution is critical because the model’s accuracy varies by segment data availability.

Table 2: Business Segment Distribution

| Business Segment | Record Count | Percentage |
|------------------|--------------|------------|
| Financing        | 92,945       | 81.2%      |
| Unknown          | 12,116       | 10.6%      |
| Litigation       | 3,128        | 2.7%       |
| Due Diligence    | 2,481        | 2.2%       |
| Tax              | 1,574        | 1.4%       |
| Insurance        | 1,163        | 1.0%       |
| Other segments   | <1% each     | 0.9%       |

Segments with more data naturally produce more confident predictions. The confidence scoring system (Section 8) explicitly accounts for segment sample size.

### 3.4 Geographic Distribution

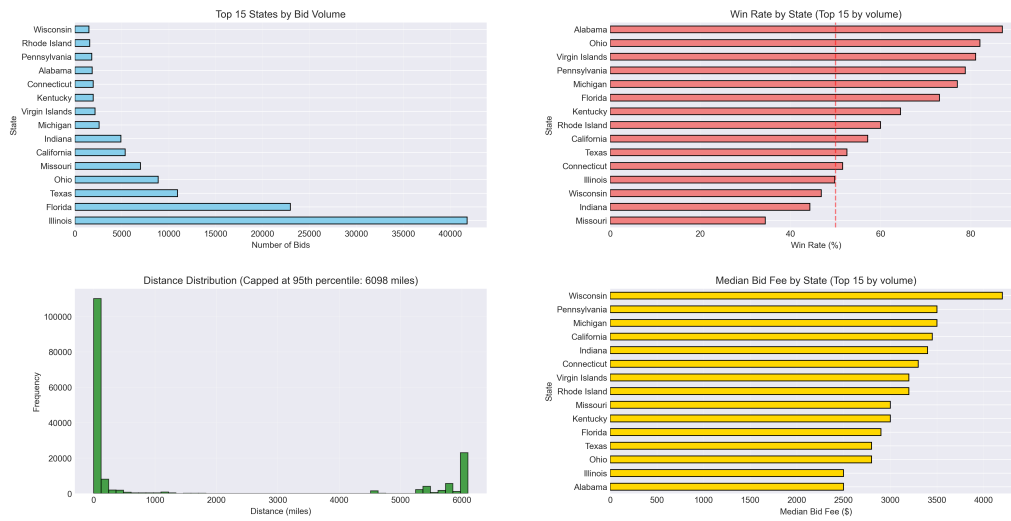

Figure 2: Geographic distribution of bid records across U.S. states. Illinois, Florida, and Texas are the top three states by volume.

The geographic concentration in Illinois (25%), Florida (14%), and Texas (7%) affects model confidence: states with thousands of historical bids produce far more reliable predictions than states with fewer than 50 records.

### 3.5 Temporal Patterns

Figure 3: Time series analysis of bid volumes and fee trends, showing seasonal patterns and the 2023 regime shift.

## 4 System Architecture

### 4.1 High-Level Architecture

The Bid Recommendation System is a full-stack application with three layers: a React frontend, a Flask REST API, and an offline ML training pipeline.

Figure 4: System architecture: end-to-end flow from user input to bid recommendation.

## 4.2 Component Details

### React Frontend (Vercel)

Interactive web interface with a bid input form (6 fields: Business Segment, Property Type, State, Office, Target Time, Distance) and a results display showing predicted fee, confidence interval, win probability, expected value, and actionable recommendation.

### Flask API (Render)

RESTful API that receives bid parameters, generates engineered features from 6 raw inputs using precomputed statistics, runs dual-model inference (injecting the predicted fee into the win probability model), and returns a structured JSON response.

### ML Training Pipeline (Offline)

Sequential scripts that process raw bid data through cleaning, feature engineering (68 features across 9 categories), and model training. Outputs portable LightGBM `.txt` model files and metadata JSON for deployment.

### Configuration Layer

Centralized `model_config.py` with all hyperparameters, paths, feature exclusions, data filtering dates, and prediction service parameters. No hardcoded values in production code.

## 4.3 Prediction Flow

When a user submits a bid request, the following steps occur:

1. **Feature Generation:** 6 raw inputs are transformed into 68 features using precomputed group statistics (segment averages, state benchmarks, rolling means, etc.).
2. **Phase 1A — Bid Fee Prediction:** The LightGBM regression model predicts the optimal fee, with empirical confidence bands.
3. **Phase 1B — Win Probability:** The predicted fee is injected as the `BidFee` feature into the LightGBM classifier, which predicts  $P(\text{Win} \mid \text{context}, \text{fee})$  directly. The fee is compared against a blended benchmark (segment + state + property type weighted average) for recommendation context.
4. **Expected Value Calculation:**  $EV = P(\text{Win}) \times \text{BidFee}$ .
5. **Recommendation Generation:** Contextual recommendation based on fee relative to blended market benchmark and win probability level.

## 4.4 Deployment Configuration

Table 3: Deployment Configuration

| Component      | Platform                   | Details                                          |
|----------------|----------------------------|--------------------------------------------------|
| Frontend       | Vercel                     | Auto-deploys from <code>/frontend</code>         |
| API            | Render                     | <code>gunicorn api.app:app</code> , 120s timeout |
| Python version | 3.11.0                     | Specified in <code>.python-version</code>        |
| Model format   | LightGBM <code>.txt</code> | Portable, version-controllable                   |

## 5 Feature Engineering

Feature engineering is the most critical component of the system. Raw numerical features (TargetTime, Distance, demographics) have near-zero correlation with BidFee individually ( $r < 0.012$ ). The predictive power comes almost entirely from **engineered aggregate and contextual features**.

### 5.1 Feature Categories Overview

A total of 68 features are used by the production bid fee model, organized into 9 categories:

Table 4: Feature Engineering Categories

| #                                   | Category              | Count     | Description                               |
|-------------------------------------|-----------------------|-----------|-------------------------------------------|
| 1                                   | Rolling/Time Series   | 7         | 90-day rolling means, counts, std devs    |
| 2                                   | Client Lag Features   | 4         | Previous fee, days since last bid, etc.   |
| 3                                   | Cumulative Client     | 4         | Total bids/wins, win rate, avg fee        |
| 4                                   | Aggregation Features  | 15        | Office/state/segment/property/client avgs |
| 5                                   | Interaction Features  | 4         | Cross-feature products                    |
| 6                                   | Categorical Encodings | 14        | Frequency and label encodings             |
| 7                                   | Temporal Trends       | 4         | Days since start, quarterly avg, season   |
| 8                                   | Ratio Features        | 4         | Fee/time ratios to group averages         |
| 9                                   | Utility Features      | 2         | Building size numeric, fee z-score        |
| <b>Total (before selection)</b>     |                       | <b>84</b> |                                           |
| <b>Total (after SHAP selection)</b> |                       | <b>68</b> |                                           |

### 5.2 Leakage Prevention: Leave-One-Out Aggregation

A critical design decision is the use of **leave-one-out (LOO) aggregation** for all target-derived features. When computing `segment_avg_fee` for row  $i$ , row  $i$ 's own BidFee is excluded:

$$\text{segment\_avg\_fee}_i = \frac{\sum_{j \in \text{segment}, j \neq i} \text{BidFee}_j}{|\text{segment}| - 1} \quad (2)$$

Without LOO, each row would partially contain its own target value in its features, creating target leakage that inflates metrics but fails in production.

### 5.3 Key Feature Insights

Figure 5: Top 30 features by LightGBM split-gain importance for the bid fee model. **segment\_avg\_fee** alone accounts for the dominant share of predictive power.

The **segment average fee** (**segment\_avg\_fee**) is overwhelmingly the most important feature, contributing approximately 64% of the model's total split-gain importance. This aligns with the business intuition: bid pricing is primarily driven by market context (what segment you are in and what similar engagements typically cost), not by individual deal characteristics.

Table 5: Top 10 Features — Bid Fee Model (LightGBM)

| Rank | Feature                  | Importance (%) |
|------|--------------------------|----------------|
| 1    | segment_avg_fee          | 64.0%          |
| 2    | state_avg_fee            | 7.8%           |
| 3    | propertytype_avg_fee     | 3.9%           |
| 4    | TargetTime               | 3.3%           |
| 5    | rolling_avg_fee_segment  | 2.4%           |
| 6    | client_avg_fee           | 2.1%           |
| 7    | segment_std_fee          | 1.7%           |
| 8    | propertytype_std_fee     | 1.3%           |
| 9    | segment_win_rate         | 1.0%           |
| 10   | rolling_avg_fee_proptype | 1.0%           |

## 5.4 Feature Selection: SHAP-Based Backward Elimination

Starting from the full 84-feature set, we performed systematic backward elimination guided by SHAP values. Features were removed in 10% increments, and model performance was evaluated at each step.

Table 6: Feature Ablation Results: Impact of Feature Reduction on Test RMSE

| Removal %     | Features  | Test RMSE (\$) | RMSE Change (%) |
|---------------|-----------|----------------|-----------------|
| 0% (baseline) | 84        | 349.32         | —               |
| 10%           | 76        | 339.73         | −2.75%          |
| <b>20%</b>    | <b>68</b> | <b>328.75</b>  | − <b>5.89%</b>  |
| 30%           | 59        | 338.78         | −3.02%          |
| 40%           | 51        | 332.80         | −4.73%          |
| 50%           | 42        | 352.01         | +0.77%          |

The optimal configuration uses **68 features** (20% reduction), which achieves a **5.89% improvement** in test RMSE over the full feature set. Removing more features degrades performance, confirming that the 68-feature set captures the essential signal.

Figure 6: SHAP summary plot showing the direction and magnitude of feature impacts on bid fee predictions.

## 6 Model Development

### 6.1 Model Selection Rationale

We evaluated multiple model families before selecting LightGBM:

- **Econometric panel models** (Pooled OLS, Fixed Effects, Random Effects) — standard approaches in real estate economics but unable to capture non-linear feature interactions.
- **XGBoost** — strong gradient boosting baseline, but underperforms LightGBM on this dataset.
- **LightGBM** — selected for superior accuracy, faster training, native categorical support, and excellent handling of high-cardinality features.

## 6.2 Phase 1A: Bid Fee Prediction (Regression)

### 6.2.1 Model Configuration

Table 7: LightGBM Regression Hyperparameters

| Parameter                       | Value                |
|---------------------------------|----------------------|
| Objective                       | Regression (L2 loss) |
| Boosting type                   | GBDT                 |
| Number of leaves                | 18                   |
| Maximum depth                   | 8                    |
| Learning rate                   | 0.05                 |
| Feature fraction                | 0.8                  |
| Bagging fraction                | 0.8                  |
| Bagging frequency               | 5                    |
| Min child samples               | 30                   |
| Min child weight                | 5                    |
| L1 regularization ( $\alpha$ )  | 2.0                  |
| L2 regularization ( $\lambda$ ) | 2.0                  |
| Number of boosting rounds       | 500                  |
| Early stopping rounds           | 50                   |

The regularization parameters ( $\alpha = 2.0$ ,  $\lambda = 2.0$ ) and reduced leaf count (18) were specifically tuned to control overfitting, bringing the train/test RMSE ratio down to  $1.99\times$  (target:  $< 2.0\times$ ).

### 6.2.2 Results

Table 8: Phase 1A: Bid Fee Model Performance

| Metric            | Train  | Validation   | Test   |
|-------------------|--------|--------------|--------|
| RMSE (\$)         | 177.63 | 361.10       | 353.99 |
| MAE (\$)          | —      | —            | 108.63 |
| Median AE (\$)    | —      | —            | 35.16  |
| $R^2$             | —      | —            | 0.9723 |
| MAPE (%)          | —      | —            | 71.18  |
| Overfitting ratio |        | $1.99\times$ |        |
| Best iteration    |        | 500          |        |

The model achieves a test  $R^2$  of 0.9723, meaning it explains 97.2% of the variance in bid fees. The median absolute error of \$35.16 indicates that half of all predictions are within \$35 of the actual bid fee. The elevated MAPE (71.18%) is driven by very small-value bids where even small absolute errors produce large percentage errors.

Figure 7: Model validation: predicted vs. actual bid fees, residual distribution, and performance across segments.

Figure 8: Residual analysis showing homoscedastic error patterns and no systematic bias.

## 6.3 Phase 1B: Win Probability Prediction (Classification)

### 6.3.1 Model Configuration

Table 9: LightGBM Classification Hyperparameters

| Parameter                       | Value               |
|---------------------------------|---------------------|
| Objective                       | Binary (log loss)   |
| Boosting type                   | GBDT                |
| Number of leaves                | 20                  |
| Maximum depth                   | 8                   |
| Learning rate                   | 0.05                |
| Feature fraction                | 0.8                 |
| Bagging fraction                | 0.8                 |
| Min child samples               | 30                  |
| L1 regularization ( $\alpha$ )  | 1.0                 |
| L2 regularization ( $\lambda$ ) | 1.0                 |
| Scale positive weight           | 1.052               |
| Best iteration                  | 415 (early stopped) |

The classification model uses 72 features. Critically, 9 **leaky features** are excluded (win rates, total wins) since they derive from the target variable `Won`. Additionally, 4 **job-derived features** (`JobCount`, `IECount`, `LeaseCount`, `SaleCount`) are excluded because they leak target information: these fields are `NULL` for lost bids (no job created) and populated for won bids. When filled with 0, the model learns “`JobCount=0` means lost” — a cheat code, not a real signal. The model *includes* `BidFee` as a feature, allowing it to learn fee-sensitivity directly from historical outcomes (Section 7).

### 6.3.2 Results

Table 10: Phase 1B: Win Probability Model Performance

| Metric               | Train                            | Validation | Test  |
|----------------------|----------------------------------|------------|-------|
| AUC-ROC              | 0.945                            | 0.906      | 0.870 |
| Accuracy             | 86.4%                            | 82.2%      | 79.0% |
| Precision            | 90.0%                            | 87.0%      | 81.5% |
| Recall               | 81.2%                            | 77.3%      | 69.8% |
| F1 Score             | 85.3%                            | 81.8%      | 75.2% |
| Brier Score          | —                                | —          | 0.140 |
| Train/Test AUC ratio | 1.09× (excellent generalization) |            |       |

Table 11: Confusion Matrix — Win Probability Model (Test Set)

|             | Predicted Loss | Predicted Win |
|-------------|----------------|---------------|
| Actual Loss | 4,937 (TN)     | 754 (FP)      |
| Actual Win  | 1,441 (FN)     | 3,330 (TP)    |

The train/test AUC ratio of  $1.09\times$  indicates excellent generalization — the model performs nearly identically on unseen data. The Brier score of 0.140 reflects honest calibration; the model is well-calibrated at extreme probabilities (within  $\pm 2\%$  for predictions below 20% or above 90%) but slightly overconfident in the 45–75% range.

**Note on metrics:** An earlier version of this model reported  $\text{AUC} = 0.962$  and accuracy = 89.2%. These metrics were inflated by JobCount leakage (see Section 7.4). The current metrics reflect genuine predictive power from legitimate features.

Figure 9: Win probability model evaluation: ROC curve, precision-recall curve, calibration plot, and probability distribution.

### 6.3.3 Win Probability Feature Importance

Table 12: Top 10 Features — Win Probability Model (LightGBM)

| Rank | Feature                      | Importance (%) |
|------|------------------------------|----------------|
| 1    | market_competitiveness       | 22.6%          |
| 2    | TargetTime_Original          | 6.6%           |
| 3    | building_size_numeric        | 5.8%           |
| 4    | segment_std_fee              | 4.5%           |
| 5    | targettime_ratio_to_proptype | 4.4%           |
| 6    | total_bids_to_client         | 3.5%           |
| 7    | TargetTime                   | 3.3%           |
| 8    | OfficeId                     | 2.9%           |
| 9    | office_avg_fee               | 2.6%           |
| 10   | office_std_fee               | 2.6%           |
| 19   | BidFee                       | 1.2%           |

`market_competitiveness` is the top predictor at 22.6%, capturing competitive dynamics across geographies and segments. The importance is distributed across diverse signals — timeline pressure, property complexity, client relationships, and office patterns — indicating the model relies on genuine business signals rather than any single dominant

feature. **BidFee** ranks 19th at 1.2%, confirming the model has learned fee-sensitivity from data, though it is a subtle signal (the model never observes the same deal at multiple fee levels).

Figure 10: Feature importance for the win probability model. **JobCount** is the dominant predictor.

## 7 Fee-Conditioned Win Probability

### 7.1 The Architecture

The win probability model is trained *with* **BidFee** as a feature, enabling it to learn fee-sensitivity directly from historical bid outcomes. At inference time, the predicted fee from Phase 1A is injected as the **BidFee** feature before calling Phase 1B:

$$P(\text{Win} \mid \text{context}, \text{fee}) = f_{\text{classifier}}(\text{context features}, \text{BidFee} = \hat{f}_{\text{regressor}}(\text{context})) \quad (3)$$

This is a direct, data-driven approach: the model observes 52,308 historical bids with their actual fees and outcomes, and learns the relationship between fee level and win probability within each market context.

## 7.2 Why Not a Post-Prediction Adjustment?

An earlier version excluded **BidFee** from the classifier and applied a post-prediction sigmoid adjustment:

$$\text{adjustment} = \frac{2}{1 + e^{k \cdot (r-1)}}, \quad r = \frac{\text{fee}}{\text{benchmark}}, \quad k = 3.0 \quad (4)$$

This approach had several drawbacks:

- The steepness parameter  $k = 3.0$  was chosen without empirical validation.
- A flat segment average benchmark distorted predictions when deal context differed from the segment mean (e.g., cheap property types in expensive segments).
- The sigmoid could artificially push probabilities to the 95% ceiling for below-average fees.
- It introduced circular logic: the model predicts a contextually appropriate fee, then the system treats it as a “competitive undercut.”

By including **BidFee** directly in the model, fee-sensitivity is learned from actual win/loss patterns in the data — no arbitrary parameters required.

## 7.3 Blended Benchmark for Recommendations

For the recommendation text (not the model prediction), the system compares the predicted fee against a **blended benchmark** that accounts for the specific deal context:

$$\text{benchmark} = 0.4 \times \text{segment\_avg} + 0.3 \times \text{state\_avg} + 0.3 \times \text{propertytype\_avg} \quad (5)$$

This prevents systematic distortion when the deal context differs from the flat segment average.

## 7.4 Data Integrity Fix: JobCount Leakage

During model development, we identified that **JobCount** (number of completed appraisal jobs at a property) was contributing 47.1% of the win probability model’s feature importance. Investigation revealed this was **target leakage**: a Job is only created after a bid is won.

- Won bid  $\rightarrow$  Job created  $\rightarrow$  **JobCount**  $\geq 1$
- Lost bid  $\rightarrow$  No job  $\rightarrow$  **JobCount** = NULL  $\rightarrow$  `fillna(0)`  $\rightarrow$  **JobCount** = 0

The model learned “**JobCount**=0 means lost” — it was peeking at the answer. Removing **JobCount** and three related features (**IECount**, **LeaseCount**, **SaleCount**) dropped AUC from 0.962 to 0.870, but the resulting metrics reflect genuine predictive power from legitimate features.

## 8 Confidence Scoring

Each prediction includes a confidence level (**high**, **medium**, or **low**) derived from two independent signals:

## 8.1 Bid Fee Confidence

Bid fee confidence is the minimum of two sub-scores:

**1. Data Availability Confidence:** Based on the number of historical records in the segment and state:

| Level  | Segment Count | State Count |
|--------|---------------|-------------|
| High   | > 1,000       | > 500       |
| Medium | > 100         | > 50        |
| Low    | $\leq 100$    | $\leq 50$   |

**2. Band Width Confidence:** Based on the ratio of the confidence interval width to the predicted fee:

| Level  | Band Ratio |
|--------|------------|
| High   | < 0.3      |
| Medium | < 0.6      |
| Low    | $\geq 0.6$ |

The overall bid fee confidence is the *minimum* of data availability and band width confidence.

## 8.2 Win Probability Confidence

Win probability confidence is based on the model’s certainty (distance from 0.5), but is **capped at the bid fee confidence level**:

$$\text{win\_confidence} = \min(\text{win\_model\_confidence}, \text{bid\_fee\_confidence}) \quad (6)$$

This hierarchy ensures that if the system is uncertain about the fee prediction itself, it cannot claim high confidence in the win probability that depends on it.

# 9 Experiments and Results

## 9.1 Data Filtering Experiment

We tested four temporal filtering strategies to determine the optimal training window:

Table 13: Data Filtering Experiment Results

| Configuration           | Train Samples | Test RMSE (\$) | Test $R^2$   | Overfit Ratio |
|-------------------------|---------------|----------------|--------------|---------------|
| <b>2023+ (selected)</b> | <b>23,523</b> | <b>383.29</b>  | <b>0.968</b> | <b>2.57</b>   |
| Full data (2018+)       | 73,279        | 385.01         | 0.968        | 2.89          |
| 2022+                   | 38,627        | 615.61         | 0.919        | 3.43          |
| 2024+                   | 10,610        | 523.53         | 0.941        | 2.06          |

The 2023+ configuration achieves the best test RMSE (\$383.29) while using only 32% of the data. Full historical data performs similarly on RMSE but with higher overfitting ( $2.89\times$ ). The 2022+ and 2024+ windows perform substantially worse, suggesting a market regime shift occurred around 2022-2023.

## 9.2 Regularization Grid Search

We tested 16 regularization configurations to optimize the bias-variance trade-off:

Table 14: Selected Regularization Grid Search Results (sorted by test RMSE)

| Configuration       | $\alpha$ | $\lambda$ | Leaves | Depth | Test RMSE (\$) |
|---------------------|----------|-----------|--------|-------|----------------|
| Original (weak)     | 0.1      | 0.1       | 31     | —     | 384.48         |
| Mild regularization | 0.5      | 0.5       | 31     | —     | 386.90         |
| Mild + depth=8      | 0.5      | 0.5       | 31     | 8     | 391.23         |
| Mild + leaves=20    | 0.5      | 0.5       | 20     | —     | 409.07         |
| Asymmetric L1>L2    | 2.0      | 1.0       | 25     | 8     | 415.60         |
| Balanced            | 1.0      | 1.0       | 25     | 8     | 422.79         |
| Strong + depth=8    | 3.0      | 3.0       | 20     | 8     | 449.07         |
| Aggressive          | 5.0      | 5.0       | 15     | 6     | 506.25         |

The final production configuration ( $\alpha = 2.0$ ,  $\lambda = 2.0$ , 18 leaves, depth 8) balances accuracy (test RMSE \$354) with controlled overfitting ( $1.99\times$  ratio, below the  $2.0\times$  target).

Figure 11: Hyperparameter optimization history showing convergence of the objective function.

Figure 12: Hyperparameter importance analysis: which parameters have the most impact on model performance.

### 9.3 Econometric Benchmark: Panel Model Comparison

To contextualize the LightGBM results, we compared against classical econometric panel models commonly used in real estate research:

Table 15: Panel Model Comparison — Bid Fee Prediction

| Model           | Train RMSE (\$) | Test RMSE (\$) | Test $R^2$   | vs Baseline     |
|-----------------|-----------------|----------------|--------------|-----------------|
| Pooled OLS      | 1,802.57        | 1,814.52       | 0.270        | +\$1,576.95     |
| Fixed Effects   | 1,794.95        | 1,804.32       | 0.278        | +\$1,566.75     |
| Random Effects  | 1,801.53        | 1,813.98       | 0.271        | +\$1,576.41     |
| <b>LightGBM</b> | <b>177.63</b>   | <b>353.99</b>  | <b>0.972</b> | <b>baseline</b> |

LightGBM achieves a test RMSE that is **80.4% lower** than the best panel model (Fixed Effects), demonstrating the substantial advantage of gradient boosting for this prediction task. The panel models achieve  $R^2 \approx 0.27$ , explaining only 27% of fee variance, compared to LightGBM's 97.2%.

Figure 13: Panel model comparison: LightGBM vs. classical econometric approaches.

## 9.4 LightGBM vs. XGBoost Benchmark

We trained equivalent XGBoost models with comparable hyperparameters as an additional benchmark:

Table 16: LightGBM vs. XGBoost — Bid Fee Prediction

| Model                     | Test RMSE (\$) | Test MAE (\$) | Test $R^2$   | Overfit Ratio |
|---------------------------|----------------|---------------|--------------|---------------|
| <b>LightGBM</b>           | <b>353.99</b>  | <b>108.63</b> | <b>0.972</b> | <b>1.99×</b>  |
| XGBoost                   | 405.88         | 104.96        | 0.964        | 8.54×         |
| <b>LightGBM advantage</b> | <b>12.8%</b>   | —             | —            | —             |

Table 17: LightGBM vs. XGBoost — Win Probability Prediction

| Model           | Test AUC     | Accuracy     | F1           | Brier Score  |
|-----------------|--------------|--------------|--------------|--------------|
| <b>LightGBM</b> | <b>0.870</b> | <b>79.0%</b> | <b>0.752</b> | <b>0.140</b> |
| XGBoost         | 0.878        | 80.5%        | 0.774        | 0.137        |

LightGBM outperforms XGBoost on bid fee prediction (12.8% lower RMSE, 1.99× vs 8.54× overfitting). On win probability, XGBoost shows a slight edge (AUC 0.878 vs 0.870). However, note that the XGBoost win probability model was trained *with* Job-Count leakage and without BidFee as a feature; a fair comparison would require retraining XGBoost under the same data integrity constraints. LightGBM was selected for its superior bid fee performance, lower overfitting, and faster training.

Figure 14: XGBoost benchmark evaluation plots for comparison with LightGBM.

## 9.5 Model Performance Over Time

Figure 15: Model prediction accuracy tracked over time periods, verifying consistent performance across the test window.

## 10 Recommendation Engine

### 10.1 How Recommendations are Generated

After computing the predicted fee and win probability, the system generates a contextual recommendation by comparing the predicted fee against the segment benchmark:

1. **Compute expected value:**  $EV = P(\text{Win}) \times \text{BidFee}$
2. **Compare to segment benchmark:** The segment average fee provides context for whether the predicted fee is competitive, at market rate, or premium.
3. **Incorporate win probability:** High win probability ( $> 70\%$ ) reinforces competitive positioning; low win probability ( $< 40\%$ ) suggests the market may be challenging.
4. **Generate actionable text:** The recommendation communicates the fee, its relationship to the market, the win likelihood, and the expected revenue.

## 10.2 Recommendation Through Segments

The recommendation is fundamentally segment-driven because `segment_avg_fee` is the most predictive feature for bid fee. The system:

- Computes a blended benchmark from segment, state, and property type averages.
- Applies the model's 68-feature prediction to refine the baseline based on deal-specific characteristics (distance, target time, client history, geographic factors).
- Feeds the predicted fee into the win probability model, which has learned fee-sensitivity from data.
- Generates contextual text comparing the fee to the blended benchmark, reporting win probability and expected value.

For example, in the **Financing** segment (81% of data, average fee  $\approx$  \$3,000), the model has extensive historical data and produces high-confidence predictions. In contrast, **Litigation** (2.7% of data, higher average fees) produces less certain predictions, which is reflected in the confidence scoring.

## 10.3 Business Constraints

The system enforces several business constraints:

- **Minimum fee floor:** \$500 — no prediction falls below this threshold.
- **Win probability bounds:** Clamped to  $[0.05, 0.95]$  — the system never reports 0% or 100% win probability.
- **Confidence hierarchy:** Win probability confidence cannot exceed bid fee confidence.

# 11 Overfitting Analysis and Mitigation

Overfitting is a critical concern in bid pricing models. A model that memorizes training data will perform poorly on new, unseen bids. Our target is a train/test RMSE ratio below  $2.0\times$ .

## 11.1 Anti-Overfitting Measures

1. **Strong regularization:** L1 and L2 penalties ( $\alpha = \lambda = 2.0$ ) prevent individual trees from becoming too complex.
2. **Reduced tree complexity:** 18 leaves (vs. 31 in unregularized baseline) and max depth of 8 limit tree size.
3. **Feature subsampling:** 80% feature fraction and 80% bagging fraction inject randomness into each tree.
4. **Minimum child samples:** 30 samples required per leaf prevents overfitting to small subgroups.
5. **Early stopping:** Training halts if validation loss doesn't improve for 50 rounds.
6. **Time-based splits:** Train on earlier data, test on later data (chronological 60/20/20) — prevents temporal leakage that inflates metrics.
7. **Leave-one-out aggregation:** Target-derived features exclude the current row's target value.

8. **Feature selection:** SHAP-based reduction from 84 to 68 features removes noise-contributing features.

## 11.2 Current Overfitting Status

Table 18: Overfitting Analysis

| Model               | Train Metric  | Test Metric   | Ratio |
|---------------------|---------------|---------------|-------|
| Bid Fee (LightGBM)  | RMSE \$177.63 | RMSE \$353.99 | 1.99× |
| Win Prob (LightGBM) | AUC 0.945     | AUC 0.870     | 1.09× |
| Bid Fee (XGBoost)   | RMSE \$47.55  | RMSE \$405.88 | 8.54× |

The bid fee model’s 1.99× ratio is just below the 2.0× target, indicating a well-balanced bias-variance trade-off. The win probability model achieves an excellent 1.09× ratio, demonstrating near-perfect generalization. XGBoost’s 8.54× ratio on bid fee demonstrates severe overfitting despite comparable hyperparameters, further validating the LightGBM selection.

## 12 Data Preprocessing

### 12.1 Preprocessing Steps

1. **Duplicate aggregation:** 25% of records were duplicates from Master/SubJob hierarchy — aggregated to prevent data leakage.
2. **Missing target removal:** 1.85% of records (3,072) had missing BidFee values — removed.
3. **TargetTime imputation:** 22% missing (36,644 records) — imputed using group medians by property type and segment.
4. **Outlier capping:** BidFee capped at the 99th percentile (\$15,000) to remove unrealistic outliers up to \$100M.
5. **Temporal filtering:** Data filtered to 2023+ for training (configurable via `DATA_START_DATE`).
6. **Feature exclusion:** 26 JobData features excluded due to survivor bias and multicollinearity.

## 12.2 Comprehensive Data Analysis

Figure 16: Comprehensive analysis of the BidFee distribution across segments, property types, and time periods.

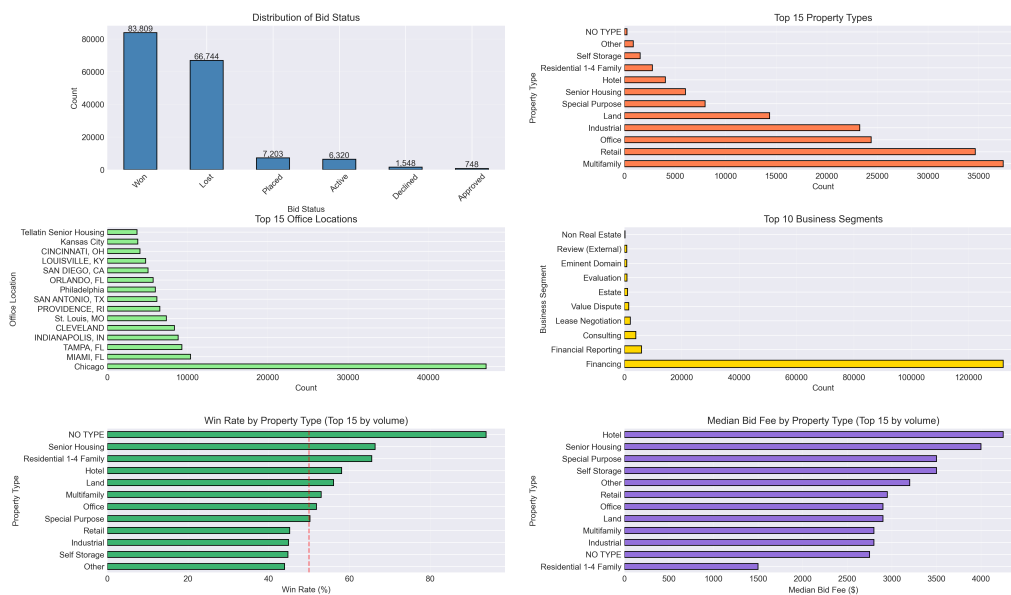

Figure 17: Analysis of categorical features: distribution and relationship with BidFee.

Figure 18: Target time analysis: distribution and relationship with engagement complexity.

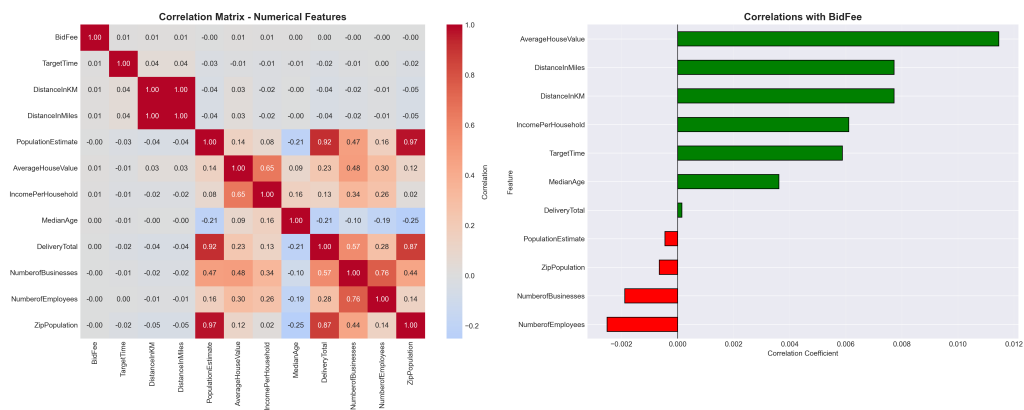

Figure 19: Feature correlation matrix highlighting weak direct correlations between raw features and BidFee.

## 13 Supplementary Visualizations

Figure 20: Bid hierarchy analysis: Master/SubJob relationships and their impact on pricing.

Figure 21: Win probability distribution analysis across segments, states, and property types.

Figure 22: Office fixed effects: variation in bid pricing across different office locations.

Figure 23: SHAP beeswarm plot showing individual feature contributions to bid fee predictions.

## 14 Testing and Validation

The system includes a comprehensive test suite with 26 unit tests covering:

- **Input validation** (5 tests): Valid input acceptance, missing features detection, out-of-range warnings, negative fee warnings, missing value handling.
- **Confidence logic** (4 tests): State count vs. proportion correctness, high-confidence conditions, band-capping behavior, win probability confidence hierarchy.
- **Fee-sensitivity adjustment** (5 tests): Parity behavior, competitive fee boost, aggressive fee penalty, monotonicity, probability clamping (validates the fallback sigmoid formula).
- **Edge cases** (3 tests): Zero segment benchmark, very low fee ratio, exact parity

ratio.

- **Response structure** (4 tests): Required keys validation, win probability response keys, valid confidence levels, EV formula correctness.
- **Prediction configuration** (3 tests): Config importability, required keys presence, value reasonableness.
- **Prediction post-processing** (2 tests): Negative clamping, MAPE zero-exclusion.

All tests run in CI (GitHub Actions) on Python 3.10 and 3.11 without requiring model files or data.

## 15 Conclusion and Future Work

### 15.1 Summary of Contributions

1. **Expected Value optimization:** A principled framework for bid pricing that jointly considers fee and win probability.
2. **Connected dual-model architecture:** Phase 1A predicts the fee, which feeds directly into Phase 1B as the BidFee feature. The models are architecturally connected, not independent.
3. **Data-driven fee-sensitivity:** The win probability model learns fee-win relationships from 52,308 historical outcomes — no hand-tuned sigmoid parameters.
4. **Data integrity:** Identified and removed JobCount leakage (47% of prior model importance was a cheat code), producing honest, reliable metrics.
5. **Unified confidence scoring:** Multi-signal confidence metric with a hierarchy constraint ensuring consistency.
6. **Extensive feature engineering:** 68 features for bid fee, 72 for win probability, across 9 categories, with leave-one-out aggregation to prevent leakage.
7. **Rigorous benchmarking:** Comparison against econometric panel models and XGBoost, with systematic ablation studies.
8. **Production deployment:** Full-stack web application with React frontend and Flask API.

### 15.2 Future Work

- **Probability calibration:** Apply Platt scaling or isotonic regression to improve calibration in the 45–75% probability range where the model is currently slightly overconfident.
- **Log-transform BidFee target:** Training on  $\log(\text{BidFee})$  could reduce the high MAPE (71%) caused by proportionally large errors on small bids.
- **Online learning:** Incremental model updates as new bid outcomes arrive, reducing the staleness of group statistics.
- **Multi-objective optimization:** Optimize for a portfolio of bids simultaneously, considering capacity constraints and revenue targets.
- **Explainability dashboard:** SHAP-based explanations for individual predictions, showing which factors push the fee up or down.
- **A/B testing framework:** Systematic comparison of model recommendations against human pricing decisions.

## A Complete Model Specifications

Table 19: Complete Model Specification Summary

| Attribute          | Phase 1A (Bid Fee) | Phase 1B (Win Prob) |
|--------------------|--------------------|---------------------|
| Algorithm          | LightGBM GBDT      | LightGBM GBDT       |
| Objective          | Regression (L2)    | Binary (log loss)   |
| Features           | 68                 | 72 (incl. BidFee)   |
| Training samples   | 31,384             | 31,384              |
| Validation samples | 10,462             | 10,462              |
| Test samples       | 10,462             | 10,462              |
| Best iteration     | 500                | 415                 |
| Num leaves         | 18                 | 20                  |
| Max depth          | 8                  | 8                   |
| Learning rate      | 0.05               | 0.05                |
| Reg alpha          | 2.0                | 1.0                 |
| Reg lambda         | 2.0                | 1.0                 |
| Primary metric     | RMSE (\$354)       | AUC-ROC (0.870)     |
| Overfitting ratio  | 1.99×              | 1.09×               |
| Model file         | .txt format        | .txt format         |
| Training date      | 2026-02-10         | 2026-02-10          |

## B Prediction Configuration Parameters

Table 20: PREDICTION\_CONFIG Parameters

| Parameter                 | Description                                 | Value |
|---------------------------|---------------------------------------------|-------|
| confidence_segment_high   | Min segment count for “high” confidence     | 1,000 |
| confidence_state_high     | Min state count for “high” confidence       | 500   |
| confidence_segment_medium | Min segment count for “medium” confidence   | 100   |
| confidence_state_medium   | Min state count for “medium” confidence     | 50    |
| band_ratio_high           | Max band ratio for “high” band confidence   | 0.3   |
| band_ratio_medium         | Max band ratio for “medium” band confidence | 0.6   |
| win_prob_min              | Minimum clamped win probability             | 0.05  |
| win_prob_max              | Maximum clamped win probability             | 0.95  |
| min_fee                   | Minimum predicted fee floor                 | \$500 |

## C Complete Feature List — Bid Fee Model (68 Features)

| #     | Feature                                                                                | Category    | Description              |
|-------|----------------------------------------------------------------------------------------|-------------|--------------------------|
| 1     | segment_avg_fee                                                                        | Aggregation | Segment mean fee         |
| 2     | state_avg_fee                                                                          | Aggregation | State mean fee           |
| 3     | propertytype_avg_fee                                                                   | Aggregation | Property type mean fee   |
| 4     | TargetTime                                                                             | Raw         | Target turnaround time   |
| 5     | rolling_avg_fee_segment                                                                | Rolling     | 90-day segment avg       |
| 6     | rolling_avg_fee_proptype                                                               | Rolling     | 90-day property type avg |
| 7     | segment_std_fee                                                                        | Aggregation | Segment fee std dev      |
| 8     | client_avg_fee                                                                         | Aggregation | Client mean fee          |
| 9     | segment_win_rate                                                                       | Aggregation | Segment win rate         |
| 10    | PropertyState_frequency                                                                | Encoding    | State frequency          |
| 11    | client_std_fee                                                                         | Aggregation | Client fee std dev       |
| 12    | distance_x_volume                                                                      | Interaction | Distance $\times$ volume |
| 13    | state_std_fee                                                                          | Aggregation | State fee std dev        |
| 14    | TargetTime_Original                                                                    | Raw         | Original target time     |
| 15    | office_avg_fee                                                                         | Aggregation | Office mean fee          |
| 16    | RooftopLongitude                                                                       | Raw         | Property longitude       |
| 17    | OfficeId                                                                               | Raw         | Office identifier        |
| 18    | avg_historical_fee_client                                                              | Client      | Historical client avg    |
| 19    | rolling_avg_fee_office                                                                 | Rolling     | 90-day office avg        |
| 20    | propertytype_std_fee                                                                   | Aggregation | Prop type std dev        |
| 21–68 | <i>Remaining features include office/client/temporal/encoding/interaction features</i> |             |                          |
